10 (Dated: 18 December 2024)

Extensive linear and nonlinear simulations to study electron temperature gradient (ETG) stability and thermal transport in NSTX and NSTX-U plasmas were performed using the fully electromagnetic gyrokinetic code CGYRO. Linear simulations were performed to determine ETG thresholds in different discharges, showing that ETG modes in spherical tokamaks can present different scalings compared to conventional aspect-ratio tokamaks. Nonlinear gyrokinetic simulations were conducted for selected cases to calculate electron thermal transport and compare to experimental values. Results are also compared with those of ETG modes in the Multi-Mode Model (MMM) and the Trapped-Gyro-Landau-Fluid (TGLF) reduced model codes, to better understand their applicability in spherical tokamaks.

11 I. INTRODUCTION

12 Experiments on the National Spherical Torus Experiment
13 (NSTX) have demonstrated that electron thermal transport is
14 anomalous and dominates over ion thermal transport, which
15 has been reported to usually be at neoclassical levels^{1,2}. One
16 of the modes that is responsible for electron thermal trans-
17 port is the electron temperature gradient (ETG) mode^{3,4}. ETG
18 modes, which are mostly electron-scale, are the usual driv-
19 ing electron thermal transport mechanism when ion-scale tur-
20 bulence is suppressed. There is now a vast literature about
21 electron-scale turbulence (See for example Ref. 5 and refer-
22 ences therein). In particular, ETG may play a significant
23 role in the pedestal of conventional aspect ratio tokamaks
24 where, for example, they were shown to account for a sig-
25 nificant fraction of the heat flux on DIII-D⁶ and JET⁷, or
26 the ion-scale ETGs that were found to be dominant in a JET
27 discharge⁸. Along with these, there were also efforts in devel-
28 oping reduced models to improve predicting capabilities^{6,9}.
29 On the other side, ETG turbulence has been also found to
30 be relevant in spherical tokamaks (STs)^{10,11} and, in particu-
31 lar, in NSTX discharges^{12–18}. To properly model anomalous
32 transport in tokamaks and, in particular, the transport caused
33 by ETG modes, gyrokinetics is commonly used in spherical
34 tokamaks^{15,19}. This includes a validation exercise on NSTX
35 data that showed agreement between electron-scale turbulence
36 with gyrokinetic simulations¹⁷. However, it is computationally
37 expensive for fast or real-time profile reconstruction and,
38 in some cases, for profile prediction. Therefore, reduced mod-
39 els need to capture ETG physics, namely thresholds and trans-
40 port, in order to be used for predicting profiles in present and
41 future devices like NSTX and NSTX-U. Hence, validating
42 these models against gyrokinetic simulations is critical.

43 In this work, an extensive linear analysis of ETG modes
44 was carried out in NSTX plasmas. Nonlinear simulations to
45 study ETG transport were also performed for particular cases.
46 All the gyrokinetic simulations were local (flux tube) and con-
47 ducted using the CGYRO code²⁰. Four NSTX discharges and

48 one NSTX-U projection were analyzed. Figure 1 shows var-
49 ious profiles of the different analyzed discharges in this work
50 that can affect ETG stability. As can be noted, the profiles
51 cover a wide range in parameter space, which is one of the
52 purposes of this work. NSTX shots 120968 (TRANSP ID
53 120968A02), 129041 (TRANSP ID 129041A10) and 120982
54 (TRANSP ID 120982A09) were already employed in ion
55 scale analysis, and they were referred to as high, medium,
56 and low collisionality discharges²¹. The NSTX-U projec-
57 tion, based on NSTX shot 121123 (TRANSP ID 121123K55),
58 was also studied in the same work and referred to an even
59 lower collisionality regime. This is one of the main purposes
60 of NSTX-U, which aims to examine and assess transport in
61 low collisionality regimes^{22,23}. Shot 129016 (TRANSP ID
62 129016A03) was also explored previously, and on which the
63 first ETG gyrokinetic simulations in NSTX were presented¹⁵.
64 A more complete set of parameters at all the radial locations
65 analyzed in this work can be found in Table I²⁴, where stan-
66 dard definition for the various quantities is employed^{20,21}. For
67 all the simulations, three kinetic species were included: elec-
68 trons, deuterons (the main plasma ion species), and carbon as
69 the main impurity. The simulations are constrained to the core
70 region (up to $r/a = 0.8$, where r is the minor radius of the lo-
71 cal flux surface, referred here as the radial coordinate, and a
72 the minor radius of the LCFS). The NSTX pedestal region has
73 been separately investigated recently^{25–28} and therefore left
74 out of the scope of the present work.

75 This paper is organized as follows: In Sec. II, a broad set of
76 linear simulations is conducted to determine gyrokinetic ETG
77 thresholds of the different discharges and radial positions de-
78 scribed in Table I. An analysis is also conducted to put in ev-
79 idence different features that ETG may have in high- β and
80 low-aspect-ratio tokamaks. In Sec. III, a nonlinear analysis
81 is presented for one discharge showing convergence tests and
82 scans. In Sec. IV, comparison with reduced models is per-
83 formed, for both linear and nonlinear calculations, as well as
84 with experimental results obtained from power balance with
85 TRANSP code. Finally, Sec. V presents the conclusions.

This is the author's peer reviewed, accepted manuscript. However, the online version of record will be different from this version once it has been copyedited and typeset.

FIG. 2: (a) real frequency, ω_r , and (b) growth rate, γ of shot 129016 as a function of the wavenumber, $k_\theta \rho_s$, for two radial locations, $r/a = 0.6$ and 0.7 . Different modes are present. Dashed and dotted curves show ETG results with $\delta B_{||} = 0$ and $\delta A_{||} = \delta A_{||} = 0$, respectively.

86 II. LINEAR ANALYSIS AND ETG CRITICAL GRADIENTS

87 As a first step and for each discharge, fully electromagnetic
88 CGYRO²⁹ linear simulations were conducted over a wide
89 range of wavenumbers to determine the modes present at the
90 nominal experimental conditions. CGYRO uses a combina-
91 tion of spectral and pseudospectral techniques²⁰. For these
92 simulations, typical grid resolutions employed were $N_\xi = 8$
93 (energy), $N_\xi = 16$ (pitch angle) and $N_\theta = 48$ (poloidal). N_{rad} ,
94 which defines the number of ‘connected’ flux tubes, was usu-
95 ally chosen to be 6 for electron scale modes and 12 for ion-
96 scale modes, while the number of toroidal modes, N_{tor} , is
97 limited to 1 for linear simulations, and determined by the bi-
98 normal wavenumber $k_\theta \rho_s$ ($\rho_s = (m_p T_e)^{1/2} / B_{unit}$ is an effective
99 ion-sound gyroradius and B_{unit} is an effective magnetic
100 field²⁰). An example of these analysis is presented in Fig.
101 2. Figure 2 shows the (a) real frequency (in symlog scale)
102 and (b) growth rate for shot 129016 at two radial locations,
103 $r/a = 0.6$ and 0.7 , as a function of $k_\theta \rho_s$. From Fig. 2,
104 $r/a = 0.6$, the dominant mode is indicated as ETG, with other
105 modes present in the ion-scale region, including microtearing
106 modes (MTMs) and kinetic ballooning modes (KBMs), but
107 present with very small growth rates. At $r/a = 0.7$, KBM and
108 MTM are also present. The procedure to identify the ion-scale
109 modes is the same as the one presented in Ref. 21, in which
110 eigenfunctions as well as real frequency and growth rate be-

FIG. 3: Eigenfunctions of the (a) perturbed electrostatic potential, (b) the perturbed parallel vector potential, and (c) the parallel magnetic field, corresponding to a mode with $k_\theta \rho_s = 20$ (shot 129016 at $r/a = 0.6$). (d) Real frequency and (e) growth rates of modes at the same radial location, scanned over the electron temperature gradient to determine the ETG growth rate threshold.

112 havior with different parameters are analyzed to determine the
113 mode nature. However, it is important to note that in both
114 cases, the $E \times B$ flow shearing rate, γ_E , is larger and expected
115 to suppress this ion scale instability (although MTMs could
116 sometimes be unaffected by the flow shear rate as reported in
117 MAST studies³⁰ or projections to future ST power plants³¹).

118 In the electron-scale range, it can be seen from Fig. 2(b)
119 that ETG modes peak at $k_\theta \rho_s \approx 20$ ($\rho_s/a = 6.70 \times 10^{-3}$) and
120 28 ($\rho_s/a = 4.68 \times 10^{-3}$) for $r/a = 0.6$ and 0.7 , which cor-
121 responds to toroidal mode numbers, $n = k_\theta r/q$, of approx-
122 imately 1130 and 1800, respectively. The dashed and dotted
123 curves, which are only shown for this range and are al-
124 most identical, correspond to simulations with $\delta B_{||} = 0$ and to
125 electrostatic simulations ($\delta B_{||} = \delta A_{||} = 0$), respectively. This
126 comparison is in agreement with the fact that ETG can be usu-
127 ally captured well with electrostatic models. However, as it
128 will be shown below, this is not always the case in spherical
129 tokamaks. To identify the electron scale modes, a similar
130 procedure was employed. Figure 3 shows eigenfunctions
131 of the (a) perturbed electrostatic potential, $\delta\phi$, (b) perturbed
132 parallel vector potential, $\delta A_{||}$, and (c) perturbed parallel mag-
133 netic field, $\delta B_{||}$, for the mode with $k_\theta \rho_s = 20$ at $r/a = 0.6$ (all
134 the linear analysis in this section was conducted with $\theta_0 = 0$,
135 assuming this is the most unstable ETG mode). Eigenfunc-
136 tions show twisting (or ballooning) parity, which is a feature
137 of ETG modes. In addition, Fig. 3(d-e) presents a scan over
138 the electron temperature gradient scale length (we will refer
139 to this just as the temperature gradient), a/L_{Te} , for selected
140 wavenumbers, showing the sensitivity of the growth rate to
141 this parameter. These scans were conducted keeping the equi-
142 librium pressure gradient β' (i.e. $\alpha_{MHD,unit}$) fixed. Therefore,
143 the local equilibrium remained unchanged.

144 The scans presented in Fig. 3(c-d) also serves to estimate
145 the linear ETG threshold or critical gradient, defined as the

ETG instability in NSTX and NSTX-U plasmas

4

FIG. 4: ETG threshold (or critical gradient) profiles inferred from CGYRO linear simulations, $(R/L_{Te})_{ETG}^{(GK)}$, for the different analyzed discharges. The experimental nominal profile, $(R/L_{Te})^{(exp)}$, and an explicit expression derived for conventional aspect ratio tokamaks, $(R/L_{Te})_{ETG}^{(J)}$, are included for reference.

146 minimum a/L_{Te} value at which ETG growth rate arises for
 147 any wavenumber. Since it is usually numerically challenging
 148 to scan to very small growth rates, a simple linear extrapolation
 149 is employed to determine the actual ETG threshold, as
 150 indicated with the dashed lines.

151 A similar procedure as the one described for Fig. 3 was
 152 conducted for all the different discharges indicated in Table
 153 I, in which the ETG threshold was determined for the radial
 154 region $r/a = 0.4 - 0.8$. The results for each discharge are pre-
 155 sented in Fig. 4, which shows the experimental temperature

FIG. 5: ETG threshold inferred from linear CGYRO simulations for shot 129016 at $r/a = 0.6$ (a-c) and shot 120982 at $r/a = 0.8$ (d-f) as a function of the magnetic shear, s , elongation, κ , and safety factor, q . The trend observed in the first case agrees with standard ETG threshold while in the second case, different trends are observed.

156 gradient, $(R/L_{Te})^{(exp)}$, along with the ETG critical gradient
 157 (or threshold) inferred from the linear gyrokinetic simulations,
 158 $(R/L_{Te})_{ETG}^{(GK)}$. By comparing the inferred threshold from GK
 159 simulations with the experimental value, it is clear that ETG
 160 modes are present in several cases while suppressed in others.
 161 Figure 4 also includes a simple scaling expression,
 162 $(R/L_{Te})_{ETG}^{(J)} = \max\{(1 + Z_{eff}T_e/T_i)(1.33 + 1.91s/q)(1 -$
 163 $1.5\mathcal{E})(1 + 0.3rd\kappa/dr), 0.8RL_{nc}\}$, derived for conventional as-
 164 pect ratio tokamaks³². It can be observed that the $(R/L_{Te})_{ETG}^{(J)}$
 165 expression is not in good agreement with $(R/L_{Te})_{ETG}^{(GK)}$, which
 166 exposes the limitation of this formula when applied to low
 167 aspect ratio spherical tokamaks. It is important to clarify
 168 that the development of this formula was not intended for
 169 these conditions, but it has been used as a proxy in previous
 170 studies^{12,15,33}.

171 To put in evidence the complex physics that impacts the
 172 scaling properties of ETG thresholds in spherical tokamaks,
 173 scans over magnetic shear, s , elongation, κ , and safety fac-
 174 tor, q , were conducted around the equilibrium value of dif-
 175 ferent discharges (these scans were conducted keeping $\beta^* =$
 176 $-(8\pi/B_{unit}^2)dp/dr$ fixed). Figure 5 shows the results for shots
 177 129016 and 120982 at $r/a = 0.6$ and $r/a = 0.8$, respectively.
 178 It can be noted that very different behavior arises in both
 179 cases: ETG threshold increases with magnetic shear for shot
 180 129016 as it does for standard tokamaks (as inferred from the
 181 $(R/L_{Te})_{ETG}^{(J)}$ formula). However, the opposite trend occurs for

ETG instability in NSTX and NSTX-U plasmas

5

FIG. 6: (a) real frequency and (b) growth rates over a wide range of wavenumbers $k_\theta \rho_s$, corresponding to shot 120982 at $r/a = 0.8$, and scaling over the electron temperature gradient (indicated as a scaling factor, X_a/L_{Te}). The dash curve is the result when δB_\parallel is turned off in the model.

shot 120982. When scaling over elongation, both cases show a threshold from which the ETG threshold starts to increase and become sensitive to the plasma elongation. Finally, the scan over the safety factor also reveals opposite trends: the ETG threshold decreases as the safety factor increases for shot 129016, similarly to conventional tokamaks, but for shot 120982, the ETG threshold shows a critical value after which it increases. It is important to note that similar findings were already pointed out by Patel et al. ³¹ in which ETG critical gradients were explored in expected regimes of a high- β spherical tokamak fusion reactor, therefore confirming this different behavior.

The different ETG threshold behavior in shots 120982 and 129016 could be due to a number of reasons, like the large difference in safety factor, among others and should be further explored in future studies. Here, an additional analysis is presented in Fig. 6, showing (a) real frequencies and (b) growth rates over a wide range of wavenumbers, and for different electron temperature gradients, indicated with the scaling factor, X_a/L_{Te} (where “1.0” means the experimental value of $a/L_{Te} = 3.01$). As with the scans shown in Fig. 3, these scans were conducted keeping β' fixed.

It can be seen that growth rates peaking at $k_\theta \rho_s \sim 10 - 15$ are very sensitive to the electron temperature gradient, which is consistent with ETG modes. Another peak arises at $k_\theta \rho_s \sim$

FIG. 7: ETG critical temperature gradient thresholds from CGYRO linear analysis against their corresponding experimental value, combining all the analyzed discharges and radial positions.

40 after doubling the experimental nominal value of the electron temperature gradient. The dash curve shows results when δB_\parallel is turned off. Interestingly, the first peak vanishes when the parallel magnetic field perturbation is not included, while the second peak is more resilient, as it is the usual case of ETG modes. Although not shown here, all these modes present twisting or ballooning parity, and the quasilinear flux shows that the electron thermal flux, Q_e , is dominated by the electrostatic potential $\delta\phi$, as expected for ETG modes. We therefore conclude that all the modes present in Fig. 6 are ETG modes, but the first branch (meaning the modes peaking at $k_\theta \rho_s \sim 10 - 15$) requires a full electromagnetic model to drive those modes unstable. The effect of the compressional magnetic field, δB_\parallel , was already pointed out to be important to be included in gyrokinetic simulations for in high- β spherical tokamaks ³⁴. A recently study also showed the importance of the compressional magnetic field in the context of hybrid KBMs in the STEP tokamak ³⁵. Because of this, a simple formula like the ones used for conventional tokamaks might not be enough to describe ETG critical gradients in these conditions. Scaling laws for ETG threshold in spherical tokamaks should consider additional effects that arise in these regimes.

To summarize this section, Fig. 7 shows the ETG critical gradient threshold as a function of the corresponding experimental temperature gradient, combining all the analyzed discharges and radial positions. The dashed curve indicates the condition when the ETG threshold is at the experimental value of the temperature gradient. A similar summary was presented in Ref. ²¹ which clearly showed a correlation of experimental profiles with KBM threshold, while ITG thresholds were shown to be mostly above the corresponding experimental value. Here, Fig. 7 does not show a clear correlation suggesting that the ETG may not always impose a stiff limit, and therefore the critical gradient cannot be directly used to determine the electron temperature profile.

Case	N_{rad}	N_{tor}	$\Delta k_x \rho_s$	$\Delta k_\theta \rho_s$	L_x / ρ_s	L_y / ρ_s
A	96	26	1.82	3	3.5	2.1
B	144	26	1.01	3	6.2	2.1
C	144	34	1.03	2.2	6.1	2.9

TABLE II: Different CGYRO resolutions employed to test convergence. The remaining grid resolution values were: $n_\theta = 48$, $n_\xi = 16$, and $n_e = 8$.

244 III. NONLINEAR ANALYSIS

245 In this section, nonlinear gyrokinetic simulations were conducted to assess the thermal transport caused by ETG modes. 246 In particular, the analysis presented in this section is performed for shot 129016 and at $r/a = 0.6$, for which linear 247 simulations were discussed in the previous section. The next section will use the results presented here and include results 248 at $r/a = 0.7$ in order to compare them with reduced models as well as the experiment. These cases were chosen because the 249 linear analysis showed no ion-scale modes with growth rates larger than the corresponding $E \times B$ shearing rate. With this 250 criteria, and in order to simplify the computation, it is assumed that there is no ion-scale contribution to the electron thermal 251 flux, and therefore, it is important to note that the simulations were not multi-scale in the sense that ion-scale modes were 252 not included but limited to the electron scale. As a first step, a convergence analysis was performed where radial (N_{rad}) and 253 binormal (N_{tor}) grid resolution were changed. Table II shows an example of the different values chosen as well as other related 254 quantities employed in the simulations. 255

256 Figure 8(a) shows the electron thermal flux evolution during the simulations, which clearly saturates for all cases described in Table II. The horizontal dashed lines represent average values that are shown for reference. In addition, Fig. 257 8(b) shows the electron thermal flux spectra during the saturated phase. It can be observed that the turbulent cascade is well covered, with a peak around $k_\theta \rho_s \sim 9 - 10$, in agreement 258 with the linear case. 259

260 To assess the effect of the flow shearing rate, and to account for uncertainties in the nominal value of the electron temperature gradients, nonlinear simulations were performed 261 varying both quantities (keeping the equilibrium pressure gradient fixed, as in the linear simulations presented in the 262 previous section). This is shown in Fig. 9, where thermal flux spectra are presented for different values of (a) γ_E and (b) 263 a/L_T . The total flux obtained in each case is $6.3 \pm 0.3 (1\gamma_E)$, $5.8 \pm 0.2 (1.2\gamma_E)$, $4.2 \pm 0.3 (1.5\gamma_E)$, $2.6 \pm 0.2 (2\gamma_E)$ and $1.8 \pm 264 0.2 (0.8a/L_T)$, $6.3 \pm 0.3 (1a/L_T)$, $15.5 \pm 0.3 (1.2a/L_T)$. The $E \times B$ flow shear rate has a stronger impact on low- $k_\theta \rho_s$, as 265 expected, while increasing the electron temperature gradients impacts the entire spectrum since a broader range of modes 266 becomes unstable. 267

FIG. 8: Convergence test for shot 129016 at $r/a = 0.6$. (a) Total electron thermal flux evolution showing saturation for three different grid resolutions indicated in Table II. (b) Electron thermal flux spectra averaged over the time window indicated with the dashed lines in (a).

268 IV. POWER FLOW AND COMPARISON WITH REDUCED MODELS

269 In this section, linear and nonlinear CGYRO results are compared with reduced models and with values inferred from the experiments. Figure 10 shows real frequency and growth rate of the shot 129016 presented in Fig. 2 at (a-b) $r/a = 0.6$ and (c-d) $r/a = 0.7$, but compared with a reduced model developed for ETG modes, ETGM (which is part of the multi-mode model, or MMM)^{36,37}, as well as TGLF^{38,39}, which has been widely used in conventional tokamaks. Both reduced models find unstable ETG modes at this condition, in agreement with CGYRO. Here, the electrostatic (ES) model of TGLF is employed, but the electromagnetic model gives a similar linear result. Real frequencies at $r/a = 0.6$ are well reproduced by both reduced models. TGLF also reproduces the real frequency at $r/a = 0.7$ in good agreement with CGYRO, whereas ETGM shows a deviation. When looking at the growth rates, some noticeable discrepancies arise. ETGM growth rate presents a similar behavior to CGYRO matching the maximum growth rate value, although the overall trend is shifted towards lower wavenumbers. This difference may stem from the method used to incorporate finite Larmor radius (FLR) effects in the ETGM model, which relies on the norm of $\langle k_\perp \rangle$ derived from a well-localized eigenfunction. To

FIG. 9: ETG electron thermal flux spectra for (a) different $E \times B$ flow shearing rates ($\gamma_E = 0.757c_s/a$), and for (b) different values of the electron temperature gradient ($a/L_{Te} = 3.48$). Lower $k_\theta \rho_s$ modes are affected by γ_E , while a/L_{Te} affects the entire spectra.

address this discrepancy, the ETGM model's thermal diffusivity was calibrated using NSTX discharges³⁶. Once calibrated, the model maintains consistency without adjustments across different discharges⁴⁰. TGLF also presents growth rates trends similar to CGYRO but they are systematically overpredicted and not showing a maximum within the analyzed range of wavenumbers. This overprediction of TGLF was already pointed out in a recent study⁴¹. As it will be shown below, this does not necessarily reflect on higher fluxes, as they are certainly dependent on the employed saturation rule. In addition, even it is not shown here, both TGLF and ETGM do not show a clear ETG threshold as CGYRO does. When substantially reducing a/L_{Te} at $r/a = 0.6$ in both reduced models, there was always a nonzero growth rate for at least one wavenumber.

Nonetheless, the main purpose of these reduced models is to use them for profile prediction and even for real-time plasma control. This is related with the thermal energy flux and, therefore, with CGYRO nonlinear calculations. The nonlinear simulations presented in the previous section allow the calculation of the total power flow. This is presented in Fig. 11, which shows the total power flow through the (a) $r/a = 0.6$ and (b) 0.7 flux surfaces for the shot 129016. The experimental value is marked with a black star, and a 20% error bar is assumed, which is consistent with uncertainties employed previously^{15,17}. From the linear analysis presented in Fig. 2,

FIG. 10: Comparison of CGYRO linear simulations with reduced models ETGM and TGLF for shot 129016 at (a-b) $r/a = 0.6$ and (c-d) $r/a = 0.7$.

it is reasonable to expect that, for $r/a = 0.6$, all the transport is caused by ETGs, while at $r/a = 0.7$, either KBMs or MTMs can potentially play a role since they are near threshold. CGYRO results are shown with circles and for three flow shear rates in both cases (at $r/a = 0.6$, $\gamma_E = 0.757c_s/a$, and at $r/a = 0.7$, $\gamma_E = 0.403c_s/a$). Simulations are also presented as a function of the electron temperature gradient, scanning over different values, to account for experimental uncertainties. It can be observed that the comparisons with NSTX experimental data are in agreement within the uncertainties.

In addition, Fig. 11 shows results from the reduced model ETGM in squares⁴². As mentioned before, ETGM was calibrated to NSTX data, but it is worth noting again that the calibration is global and not constrained to a particular flux surface. Therefore, although the $r/a = 0.6$ surface lies within the global plasma conditions used for ETGM calibration, the agreement between ETGM results and the experimental nominal value at $r/a = 0.6$ for this particular discharge, as well as with the CGYRO simulations, is significant. This provides confidence on the use of ETGM for profile prediction in future NSTX-U discharges, but further analysis would still be valuable. The results of the reduced model TGLF (indicated with triangles) are also included for comparison, which properly identify the presence of ETG modes. For these cases, the TGLF SAT0 rule was employed and was found to perform better than the newer SAT1 or SAT2 rules, which presented a much stronger sensitivity on the electron temperature gradient and substantially over-predicted the power flow in some cases (not shown here). These newer saturation rules account for multiscale effects and might be the cause of discrepancy, as mentioned in Ref. 41, and further investigation is still necessary. The values obtained by TGLF SAT0 shows that it underpredicts the power flow at $r/a = 0.6$. At $r/a = 0.7$ the

FIG. 11: Power flow through the flux surface $r/a = 0.6$ (top) and $r/a = 0.7$ (bottom) for shot 129016 at 460ms. Experimental value is indicated with a black star with a 20% generic error bar assumed. CGYRO results are indicated with circles and colors refers to different values of the flow shearing rate, γ_E . Results from ETGM and TGLF are included in squares and triangles, respectively.

power flow matches CGYRO nominal value. However, for this radial position, a significant fraction of the electron thermal flux ($\sim 60\%$ at the nominal a/L_{Te} value) comes from low- $k_{\theta\rho_s}$ range, corresponding to ion-scale modes observed in the linear simulations. As an additional test, electron thermal flux from reduced models were calculated at $r/a = 0.8$, in which CGYRO linear analysis showed that ETG is stable at the experimental nominal value (see Fig. 4a). Although not shown here, at this radial location both ETGM and TGLF SAT0 predicts negligible electro-scale transport, as expected.

Finally, it is important to note that the scaling of the power flow with the electron temperature gradient differs between CGYRO and the reduced models. Both ETGM and TGLF exhibit similar linear scaling behavior, in contrast to CGYRO, which displays for these cases a power-law-like trend, which corresponds to a stiff transport. This discrepancy also warrants further investigation and understanding.

V. CONCLUSIONS

Extensive linear gyrokinetic simulations were conducted on several NSTX discharges and on an NSTX-U projection to analyze the occurrence and thresholds of ETG modes. The discharges covered a wide range of parameter space. ETG threshold profiles were determined, finding that the modes are usually present in some discharges while suppressed in others at the experimental value. The ETG threshold in spherical tokamaks is shown to follow a more complex physics and a simple analytic formula might not be possible since different trends are observed in different cases. Non linear simulations were also conducted for a particular discharge, showing that CGYRO results are consistent with the transport levels expected in the experiments. In addition, a comparison of gyrokinetic simulations with reduced models ETGM and TGLF, critical for fast profile prediction, was also conducted. Both ETGM and TGLF models captured ETG physics. On one side, the ETGM model has shown power flow close to experimental values, as have the CGYRO nonlinear simulations. On the other side, TGLF-SAT0 underpredicted the power flow coming from ETG modes. In addition, there are discrepancies of both reduced models compared to CGYRO, such as the lack of rollover in the TGLF growth rate, the shift of the frequency and/or growth rate in ETGM, and the lack of a well defined threshold inferred from the linear simulations in both cases. Finally, the scaling of the power flow with the electron temperature gradient shows differences between CGYRO, which shows a power-like trend corresponding to a stiff transport, and ETGM and TGLF reduced models, which show a more linear-like trend. Therefore, further comparisons would be valuable to continue understanding their applicability and limitations.

- 625 ⁴⁰In the ETGM model, the equilibrium is based on the $s - \alpha$ assumption, 680
 626 with the eigenfunction chosen as $\phi(\theta) = 1 + \cos(\theta)$ for $\theta \leq \pi$. Rather than 681
 627 solving the problem along the field line or ballooning angle θ , the norms 682
 628 of the relevant differential operators ($\langle \omega_D \rangle$, $\langle k_{\parallel} \rangle$, and $\langle k_{\perp} \rangle$) are computed 683
 629 directly⁴¹, which accelerates the eigenvalue calculations. However, this ap- 684
 630 proach shifts the ETGM growth rate spectrum towards lower wavenum- 685
 631 bers in $k_y \rho_s$, resulting in a higher ETGM diffusivity. Typically, ETG modes 686
 632 exhibit large k_y and smaller k_x ; thus, we have assumed $k_x = \frac{1}{2} k_y$ ⁴. While
- 633 modifying the estimation of k_x has a minimal impact on the shape of the 634
 635 growth rate, it significantly influences the magnitude of ETGM diffusiv- 636
 637 ity. Therefore, calibrating the ETGM thermal diffusivity using experimental 638
 639 discharge data is necessary. The calibration procedure for ETGM involved 640
 641 adjusting a calibration factor applied to the diffusivity. This calibration was 642
 643 performed globally, based on matching the overall heat flux profile to NSTX 644
 645 experimental data³⁶ and set to 0.05 (which is applied, for example, to Eq. 646
 647 (21) in Ref. 36). This global calibration is applied across entire discharges 648
 649 and remains fixed without adjustments at individual radii, demonstrating 650
 651 the model's ability to capture key transport features across a broad range of 652
 653 conditions. The model's thermal flux, as shown in Figs. 10 and 11, incor- 654
 655 porates this calibration, with no additional free parameters introduced. The 656
 657 same calibration factor is also employed when validating time-dependent 658
 659 temperature profiles in NSTX discharges³⁷. This ETGM model should de- 660
 661 scribe ETG transport in plasma regimes close to the NSTX equilibrium used 662
 663 for calibration, and is part of the MMM module used in TRANSP that is 664
 665 available for other discharges and devices. 666

- 672 ⁴²It is noted here that the $E \times B$ flow shear definition used in ETGM differs 672
 673 from the one used in CGYRO. ETGM uses the Hahn and Burrell 673
 674 definition⁴⁵⁻⁴⁷, $\gamma_E = (RB_{pol}/B_{tor})\partial_r(E_r/RB_{pol})$, whereas CGYRO (and 674
 675 therefore TGLF) uses flux surface expression introduced by Waltz and 675
 676 Miller^{48,49}, $\gamma_E = (r/q)\partial_r(E_r/RB_{pol})$. The values employed by ETGM were 676
 677 $\gamma_E = 1.14 [c_s/a]$, at $r/a = 0.6$, and $0.493 [c_s/a]$, at $r/a = 0.7$, respectively. 677
